Abstract. We will discuss the observing strategy of the *Transient High Energy Sky and Early Universe Surveyor* (THESEUS) mission proposed to ESA as a response to the M5 call for proposals. The description of THESEUS and its science goals can be found in the white paper by Amati et al. (2018).

Key words. Telescopes: X-ray – Telescopes: NIR – Gamma ray Bursts: detection – Stars: black holes –Stars: neutron – Stars: Population III – Cosmology: observations – Cosmology: early Universe – Cosmology: reionization, first stars

1. Introduction

The description of THESEUS and its science goals can be found in the white paper by Amati et al. (2018). The main requirements of the observing strategy can be summarized as follows:

– Discover at low energies (0.3–6 keV) an unprecedented high number of GRBs (especially at high redshifts), as well as a wide range of astropysical transient sources or new events in the local and remote Universe.

– Localize the detected new transient events with 0.5–1 arcmin accuracy;
– Identify the nature of the detected transients via on-board catalogs and/or high energy (> 2 keV)imaging and/or spectroscopy.
– Promptly follow-up the secure GRBs or new transient phenomena in the Near Infrared (NIR) band and determine their position with arcsecond accuracy, ad perform NIR spectroscopy and/or photometry;

- Promptly comunicate new triggers to the ground in order to enable ground/space observatories to follow-up the new transients;
- Ensure the needed pointing stability of the satellite for at least 1 ks in order to detect the longest events while the detected events are observed in the NIR band.

In order to achieve these goals the following payload instrumentation is developed and adopted (see Fig. 1):

Fig. 1. THESEUS payload.

- A Soft X–ray Imager (SXI) based on 4 Lobster–Eye telescopes with 0.3–6 keV energy band, a 0.5–1 arcmin location accuracy and a Field of View (FOV) of about 1 sr;
- An X–/Gamma–ray Imaging Spectrometer (XGIS) based on 3 coded-mask telescopes with 2 keV–20 MeV energy band, similar sensitivity to the SXI in the common energy band (2–6 keV), 5 arcmin positioning accuracy up to 50 keV, FOV covering the SXI FOV (see Fig. 2).
- An InfraRed Telescope (IRT) of 70 cm aperture, a Cassegrain geometry, 0.7–1.8 μm wavelength band, 10'×10' FOV, sensitivity H=20.6 AB mag (300 s).

- IRT observation condition of the GRB localized with SXI: when the satellite stabilization is within 1 arcsec.
- At a sensitivity limit H=18.5 (AB), 5 minute integration time is sufficient for a Low Resolution spectrum with IRT.

Fig. 2. FOV of the SXI (*inner field*) and XGIS (*outer field*).

2. Observing strategy

2.1. How to localize new transient events with SXI

The location accuracy of the SXI is illustrated in Fig. 3, in which it is simulated the capability of a Lobster-Eye telescope in the location of X–ray sources in the Large Magellanic Cloud (LMC).

The procedure we intend to adopt for the selection of new transient events with SXI is the following:

- Apply an algorithm to the SXI data in order to get an event list with position (in CCD pixels) and pulse height, for different integration times (2, 20, 200, 2000 s);
- Convert pixel positions into a local coordinate frame;
- Subtract background pattern from the histograms;
- Scan the histograms for significant peaks and extract candidate positions;
- Calculate accurate positions in the local frame;

2.2. Identification of the transient events to be followed-up by the IRT

As the SXI telescopes can be triggered by many classes of transient phenomena (e.g., flare stars, X-ray bursts, GRBs, etc.), the XGIS provides an efficient means to help the identification of the high energy transient phenomena (GRBs, Soft Gamma-ray Repeaters, Tidal Disruption Events, X-ray counterparts of Fast Radio Bursts, etc.). Thus, in parallel to the selection done with SXI Data Handling Unit (see Fig. 4), the following trigger conditions are searched:

2.2.1. XGIS trigger condition based on images

– For each XGIS unit, the current 2–30 (or 50) keV images integrated over 3 time durations (typically 1, 10, 100 s) is continuously compared with the corresponding reference images obtained by averaging the previous (typically 30) images;
– A trigger condition is satisfied if a spot in the images emerges at a significance level of at least $n\sigma$ (typically $n = 5$).

2.2.2. XGIS trigger condition based on data rate

– Continuous monitoring of the data rate in the 2–30 keV and 30–200 keV energy bands for each of the 4 modules that make each of the 3 XGIS units;
– The trigger condition is satisfied when, in one or both energy ranges, at least 3 detection modules see a simultaneous excess at a significance level of at least $n\sigma$ (typically $n = 5$) on at least one of 4 different time scales (e.g., 10 ms, 100 ms, 1 s, 10 s).

Once the time of the XGIS event direction (from images) and/or that of the data excess are sent to the OBDH (see Fig. 4), the OBDH logic selects the events to be followed-up by the IRT. These can be events that have been recognized to be unknown transients with SXI (see above) or events imaged with the XGIS that satisfy all the XGIS trigger conditions.

Fig. 3. *Top*: X–ray map of the Large Magellanic Cloud (LMC). *Bottom*: LMC image as expected from a Lobster-Eye Telescope.

– Transform the positions in global sky coordinates;
– Check SXI positions against onboard catalogues of known sources;
– Communicate unknown transients detected with SXI to the On Board Data Handling (OBDH), as shown in Fig. 4.
Fig. 4. On board logic for commanding an IRT follow-up observation.

3. How to promptly down-link the trigger results

The baseline for promptly transmitting (less than 4 min) the trigger data to ground exploits the VHF network adopted for the SVOM mission (Wei et al. 2016). In any case, during the Phase A study, other possibilities will be investigated:

- Exploitation of the *Iridium* satellite constellation now in advanced development *Iridium Next*, that would allow to transmit the trigger data in 1 min.
- Exploitation of the *European Tracking and Data Relay Satellite System* (TDRSS) now under development, that would allow to transmit the trigger data in less than 1 min.
- American TDRSS (< 1 min) in the case of an international participation by NASA.

4. Predicted detection rate of GRBs and their properties as determined with THESEUS

We expect the following:

- As far as the detection rate, we expect a number of GRBs between 300 and 700 events/year.
- For most of the distant GRBs, we expect to be capable to determine their photometric redshift with the IRT, while for the strongest ones we expect to determine their spectroscopic redshift.
- Those GRBs, for which the photometric redshift will be determined on board,

are the best candidates for study with large ground/space facilities, like E-ELT, ATHENA, etc.
- We expect that THESEUS will be capable to provide more spectroscopic redshifts in one year than *Swift* in a decade.

5. How to manage external triggers or TOO requests

The external triggers, that will be up-loaded via Malindi ground station or via the same system adopted for the downlink (see Section 3), will arrive to the OBDH and will be managed using the same logic adopted for the internal triggers (see Fig. 4).

6. Constraints on the THESEUS solar attitude angle and sky exposure map in one year

When the satellite is in Sunlight, the solar panels (see left panel of Fig. 5) provide the electrical power to all THESEUS subsystems, keeping charged the satellite batteries. In order to guarantee the needed power, the maximum offset angle between the solar panel axis and the Sun direction has to be at most ±40 degrees (see right panel of Fig. 5).

When the satellite is in the Earth shadow, other possible attitudes are in principle possible, including the Anti-Sun direction. The attitude strategy will be deeply investigated during the Phase A study.

Assuming the attitude constraints adopted in Sunlight, the exposure map of the sky in 1 year is shown in Fig. 6.

7. Ground segment

As for other ESA missions with similar profiles, it is expected that the THESEUS ground segment will comprise a Mission Operation Center (MOC) and a Science Operation Center (SOC), both led by ESA.

The MOC is usually the sole interface with the satellite, managing all spacecraft operations, uploading the telecommands, controlling the downlink of the telemetry and collecting it from the mission ground stations, as
Max Sun Attitude Angle
(SAA) = 40°

Fig. 5. *Top*: THESEUS solar panels folded at the satellite launch. *Bottom*: Range of Sun Attitude Angles (SAA) compatible with the required power.

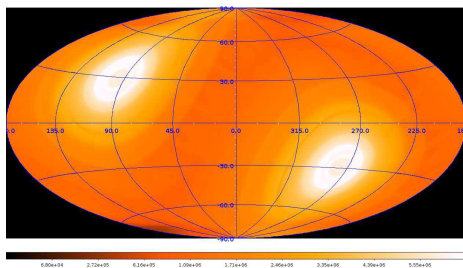

Fig. 6. Exposure map of the sky in on year, assuming the attitude constraints adopted in Sunlight (see Fig. 5)

.

well as performing all necessary maintenance and emergency operations required to guarantee the safety and nominal functioning of the spacecraft.

The SOC is usually in charge of the communications with the world-wide community, issuing the call for proposals, organizing the peer reviewed selections and compiling the yearly-long observational timeline. Being THESEUS a mission focused on GRBs and transient sources, the core of the observing program is expected to be dominated by the follow-up of these events (typical observational campaigns might comprise tens of few ks long pointings). Thus an important task will rely on the ESA appointed project scientist, who will have the final decision concerning the implementation (or not) of the target of opportunity observations (ToOs) that will be requested by the community. The largest fraction of the ToOs are expected to derive from the SXI and XGIS triggers, but, as mentioned above, a large fraction of external triggers is also expected from the other facilities operating also at different wavelengths.

For the latter, as well as for the ToOs, detailed planning constraints (e.g., sky visibility, and mission resources such as power and telemetry) will need to be identified by the SOC on a daily time scale in order to shape the short term observational schedule. A similar task will have to be covered by the MOC for what concerns the payload operations exclusion windows, on-board resources envelopes for payload operations, and final detailed checks against mission, environmental and resource constraints.

The basic Mission Planning approach for all the routine science operations phases will be built on the experience of previous missions, such as XMM-Newton, Herschel and INTEGRAL. The rapid rescheduling imposed by the GRB nature of the mission will take advantage of the heritage gained through the *Swift* mission. A THESEUS science data center (SDC) will be provided by the consortium to support the MOC and the SOC in the routinely processing, inspection, and validation of the data. The SDC is also expected to provide the required software for scientific analysis, as well as the pipelines needed for the daily data processing.

There may be different instrument operation centers (IOCs): for the XGIS, the SXI,

and the IRT. The IOCs will provide full support to ESA for the payload integration and operations, and will generally host and maintain the instrument expertize all along the mission lifetime (including the post operations). They will reasonably also provide updated calibrations for each instrument whenever required.

It is expected that a centralized archive will be hosted at SOC, functioning as the primary repository for all science data products, calibrations, documentation, and software. This will guarantee the long term exploitation of the mission data and guarantee a proper mission heritage. During the assessment phase, all available resources for the ground segment will be analyzed to optimize the ground segment design and maximize the scientific return of THESEUS.

8. Conclusions

The main science goals of the mission (the most demanding) can be achieved using the described strategy. Other technical constraints, like instrument temperature stability, attitude stability and accuracy, OBDH logic reliability, reliability of the re-pointing automatic system for a fast NIR observation, are crucial to enable the discussed observing strategy. They have been discussed in the white paper by Amati et al. (2018).
