Abstract. We present the first results of a campaign of ENZO cosmological simulations targeting the shocked and the neutral parts of the cosmic web, obtained with Supercomputing facilities provided by the INAF-CINECA agreement.

Key words. Cosmology: large-scale structures. Methods: numerical simulations

1. Introduction

Detecting the missing baryons of the cosmic web (e.g. Nicastro 2016) o and understanding the origin of cosmic magnetism (e.g. Subramanian 2016) are two pivotal goals for modern astrophysics. Detecting the radio signature of the cosmic web is also strictly related to the possibility of constraining the origin of cosmic magnetism (e.g. Vazza et al. 2017; Gheller & Vazza 2020), with potential impacts on, both, galaxy formation theory and cosmology.

As a part of a $\sim$ 10 years long campaign of simulations of the cosmic web and of its non-thermal energy components, largely supported by resources made available within the INAF-CINECA Memorandum of Understanding, we produced a new set of simulations run on the Marconi and M100 Superclusters (dubbed "ROGER" Resimulations Of the Gigaparesc-Extended Radio web).

In these models we also followed the formation of neutral Hydrogen (HI) outside of halos and in filaments, in order to use it as a signpost for missing baryons, and to cross-correlate the HI signal with the synchrotron from the shocked gas in the cosmic web. The hyper-fine structure line of HI line at 21 cm may potentially by a reliable marker of the cosmic web: while the Universe is mostly ionized at $z \leq 6$, the SKA is expected to have an enough sensitivity to detect the weak HI signal from the residual cold neutral hydrogen in filaments (Popping et al. 2015), even if recent stacking experiments have set an upper limit of $\leq 7.5\ \mu K$ on the average HI temperature from filaments connecting halos (Tramonte et al. 2019). However, both HI and synchrotron radio emission are predicted to depend on a number of physical assumptions on the origin of cosmic magnetic fields, and on the detail of cooling and feedback of baryons in large-scale structures, which makes it necessary to resort to numerical simulations in order to predict the amplitude of detectable signals in a quantitative way (Horii et al. 2017).

2. Simulations

We used the cosmological magnetohydrodynamical grid code *ENZO* (Bryan et al. 2014) to simulate 400^3, 200^3, 100^3, 50^3 and 25^3 Mpc^3 cosmic volumes, always using a static 1024^3 grid and in the concordance ΛCDM cosmology. In most runs we contrasted non-radiative ("NR") runs with a primordial uniform volume-filling comoving magnetic field $B_0 = 0.1$ nG, initialised at the beginning of the simulation ($z = 40$) with radiative run ("COOL") also including equilibrium gas cooling, and a sub-grid modelling of thermal AGN feedback, as detailed in Vazza et al. (2017). Using modules included in *ENZO*, we tracked at run-time H, H+, He, He+, He++, and electrons, and their evolution is computed by solving the rate equations with one Jacobi iteration with implicit Eulerian time discretization, with a coupling between thermal and chemical states at subcylces in the hydrodynamical timestep to evolve a number of processes (atomic line excitation, recombination, collisional excitation, free-free transitions, Compton scattering of the cosmic mi-

crowave background and photoionization from metagalactic UV backgrounds).

Our runs at CINECA used a total of $\sim$ 3 million KNL hours on Marconi and $\sim$ 2 million KNL hours on Marconi100 [1], typically using 512 cores on 64 nodes for each job. In the latter case, we took advantage of the GPU implementation of the Dedner MHD solver in *ENZO* (Wang et al. 2010), which makes cosmological static grid simulations faster by a factor $\sim 4\times$.

In post-processing, we computed synchrotron radio emission from shocked relativistic electrons and the HI signal as in Gheller & Vazza (2020); a) the spin temperature of HI is computed assuming the excitation and de-excitation by the CMB photons, the collisions with electrons and other atoms and the interactions with background Lyman-α photons (Horii et al. 2017); the HI abundance is computed in a self-consistent way by *ENZO* chemistry modules. b) The emission from relativistic electrons accelerated by diffusive shock acceleration is the convolution of the several

power-law energy distributions of electrons in the synchrotron cooling region, as in Hoeft & Brüggen (2007) and in our previous works.

3. The HI and synchrotron network of the cosmic web

Figure 1 shows composite renderings of the hot gas distribution in one of our runs, combined either with the simulated HI distribution or with the synchrotron radio emission from shocked electrons (in both cases, without observational cuts). Clearly, while all distributions are correlated with the dark matter skeleton of the cosmic web, they all fill the cosmic web in a very different way on ≤ 10 Mpc scales, leading to relatively weak spatial cross-correlation (see e.g. our recent Gheller & Vazza 2020).

As expected, the shocked gas potentially leading to radio detectable radio emission and the dense and cold gas which can promote the formation of HI sample different portions of the (mostly undetected so far) missing baryon component of the cosmic web. As shown in the left panel of Fig. 2, where we draw contours of the portions of the gas distribution that can be detected with SKA-LOW and SKA-MID surveys (Braun et al. 2019), the shocked cosmic web and the HI component only overlap at high densities, while they probe entirely different gas phases elsewhere.

For the near future, the only observable parts of these faint components may be hunted in the neighbourhood of massive halos, and to the filaments connecting them to the rest of the cosmic web (Fig. 1). A viable observational approach will thus be to focus on the terminal parts of filaments connected to halos, possibly traced via the distribution of galaxies around them (e.g. Malavasi et al. 2020).

As shown in the right panel of Fig. 2, using ROGER simulations and a new sophisticated network reconstruction to link filaments and halos, we are monitoring the typical number of filaments connected to halos, which is an increasing function of halo mass, and only

weakly dependent on the prescriptions for gas physics (Banfi et al., submitted[2]).

4. Other results and future perspectives

The topology of magnetic fields around filaments of the cosmic web has been studied by Banfi et al. (2020), where we quantified the impact of shock *obliquity* on the acceleration of cosmic ray electrons and protons (which are not accelerated by quasi-perpendicular shocks). This work highlighted that filamentary mass accretions around structures mostly develop quasi-perpendicular shocks (due to the predominant alignment of magnetic fields with the filament outer surface), possibly explaining the low level of cosmic ray proton acceleration in galaxy clusters (see also Wittor et al. 2020).

The amplitude and topology of magnetic fields simulated for six different variations of input primordial seed fields was also studied in detail in Vazza et al. (2020). In this work we discussed in depth how available (or shortly incoming) day radio surveys can already be used to constrain primordial magnetic fields, significantly improving on present constraints based on the analysis of the Cosmic Microwave Background.

In Locatelli et al. (2020), we simulated long light cones in order to forecast the typical maximum redshift which can be observed using the Dispersion Measure of Fast Radio Bursts, for different possible update configurations of the Northern Cross in Medicina.

Finally, in Vazza (2020b) we used the time analysis of medium sized runs to focus on the emergence of complex dynamical patterns in the evolving cosmic web, based on Information Theory (following Vazza 2020a).

In summary, all these works show that the signatures of rarefied gas in the cosmic web are weak and pose technical challenges to observations, as well as to theoretical models. A holistic approach to model the large-scale tracers of the cosmic web will allow radio observations to be a quantitative probe of cosmic mag-

netism, reaching the same level of detail which is expected from incoming new radio observations, and most noticeably from the Square Kilometer Array (e.g. Braun et al. 2019).

In closing, such systematic searches for the observable effects of variations in the physical models of cosmic gas require a secure access to HPC facilities over a multi-year time range, which would be hard to achieve without strategical MoU like the INAF-CINECA one that supported this program.
